**Estimating the elasticity of trade:
the trade share approach**

Abstract

Recent theoretical work on international trade emphasizes the importance of trade elasticity as the fundamental statistic needed to conduct welfare analysis. Eaton and Kortum (2002) proposed a two-step method to estimate this parameter, where exporter fixed effects are regressed on proxies for technology and wages. Within the same Ricardian model of trade, the trade share provides an alternative source of identification for the elasticity of trade. Following Santos Silva and Tenreyro (2006) both trade share and EK models are estimated using OLS and Poisson PML to test for the presence of heteroskedasticity-type-of-bias. The evidence from both specifications suggests that the bias in the OLS estimates significantly impacts the magnitude of trade cost elasticity. The welfare analysis reveals that the resulting extreme variability of the trade cost elasticity and the imposition of a common manufacturing share parameter for all countries generate substantial distortions in the calculation of benefits from trade.

I. Introduction

The elasticity of trade is a parameter which plays a key role in calculating the welfare gains from trade. Arkolakis et al. (2012) showed that within a particular class of trade models, the elasticity of trade and the share of expenditure on domestic goods are the only two parameters needed to calculate welfare gains from trade.¹ Since the import ratio is directly observable from the data, the estimation of the elasticity of trade becomes the key statistics for conducting welfare analysis.

The influential Eaton and Kortum (2002) article (henceforth EK) provides three different ways to estimate the elasticity of trade θ , all derived from their Ricardian model of trade. The first method estimates θ by relating trade variation to a proxy for trade costs. As proxy for bilateral trade frictions they use the maximum price difference across goods between countries. This one-step methodology is based on a strong assumption: the price differences cannot be larger than trade costs. A method of moments estimator gives an elasticity of 8.28, which is the EK benchmark for welfare analysis.

The same proxy for trade costs has been used by EK in another method for estimating θ . This is again a one-step methodology where a transformed version of bilateral trade is regressed on the proxy of trade costs, importer and exporter fixed effects. In this alternative specification the proxy coefficient gives a measure of the elasticity of trade parameter. The geographic terms are used as instruments for the trade costs variable in a 2SLS analysis; they obtain an elasticity of 12.86.

Simonovska and Waugh (2011) showed that these two methods lead to upward biased estimates of the elasticity of trade. To correct for this bias they propose a new simulated method of moments estimator. They apply their estimator to disaggregate price and trade-flow data for the year 2004. Their benchmark estimate for θ is 4.12, a measure which is less than a half of EK's preferred estimation.

EK estimate the elasticity of trade also with a gravity based two-step procedure. They provide a version of trade equation where a transformed bilateral trade variable is regressed on exporter technology and wages: EK modify their original trade share expression until the price of intermediaries p_i disappears from the final two-step equation. In this competitiveness equation the wage coefficient gives exactly a measure of the elasticity of trade $\mu_w = \mu_t = -\theta$. By instrumenting for wages their estimates yield

¹The trade models to which Arkolakis et al. conclusions apply are those models which feature the following assumptions: a) Dixit-Stieglitz preferences; b) one factor of production; c) linear cost functions; d) perfect or monopolistic competition along with three macro level restrictions i) trade is balanced; ii) aggregate profits are a constant share of aggregate revenues; and iii) the import demand system is CES. Among these models there are (besides the Armington model) Eaton and Kortum (2002), Krugman (1980) and variations and extensions of Melitz (2003) featuring pareto distributions of firm-level productivity.

an elasticity of 3.60. Simonovska and Waugh (2011) view this last EK estimate as reliable, since 3.60 is in line with their benchmark result.

By using the same EK Ricardian model of trade in this paper I provide an alternative source of identification for the same key parameter, θ . I directly estimate θ from the EK trade share expression, in which bilateral imports are function of technology, wages and prices other than geographic barriers. As Head and Mayer (2013) pointed out, the key difference is that in the trade share expression the wage elasticity is $\mu_w = -\beta\theta$ whereas the trade elasticity is $\mu_t = -\theta$. Thus, by calculating the average labor share in gross manufacturing production in the sample, β , the effect of wage variation on estimated exporter fixed effects gives an alternative source of identification for trade elasticity.

In the EK two-step procedure the absence of bias in the first stage coefficients is crucial to obtain unbiased estimates of the trade cost elasticity parameter. Anderson and Yotov (2010b) argue that since the gravity system identifies only relative trade costs, their finding of a very high correlation between Poisson PML and the OLS estimates suggests that the two sets of coefficients are equally good proxies for the unobservable bilateral trade costs and can be used interchangeably in the calculation of important parameters such as multilateral resistances. The competitiveness equation, however, utilises exporter fixed effects as dependent variable and a bias in the first stage estimations is likely to affect the outcome of the second step regression. With equally high correlation between Poisson PML and OLS estimates, the statistics show that the heteroskedasticity-type-of-bias of the OLS first stage results substantially affects the magnitude of the resulting trade elasticity parameter.

The resulting variability of θ significantly impacts the measure of benefits from trade. The statistics reveal that a relatively small change of θ due to heteroskedasticity-type-of-bias produces important variations in terms of welfare gains. By following Eaton and Kortum (2012) welfare calculation methodology, benefits from trade depend also on the manufacturing share of final spending. EK and Eaton and Kortum (2012) impose a common manufacturing demand share α across countries. Since α varies by country, utilising common values such as the sample mean for all countries may create distortions in the calculations of welfare gains. The evidence indicates that these distortions radically change the outcome of benefits from trade.

The following section outlines the EK model. The first part of Section 3 illustrates some key definitions useful for a better understanding of the model and the data needed for the estimations. The last part describes the resulting econometric specifications and the estimation techniques employed in this analysis. Section 4 begins by replicating the EK two-step empirical analysis for 1997. The second step dependent variable is obtained from first stage regressions estimated using both OLS and Poisson PML. The statistics indicate that the first stage results estimated with OLS suffer from heteroskedasticity-type-of-bias; since the first stage fixed effects are used as second

stage dependent variable, this bias is transferred to the estimates of trade cost elasticity. Subsequently, the two-step results are compared to the estimates obtained through the one-step procedure, in order to establish which methodology performs best. Then, I discuss the estimated parameters from the EK benchmark model and contrast the results with the trade share estimations. The comparison indicates that the θ parameter obtained from the competitiveness equation is reliable only if estimated with econometric techniques, such as Poisson PML, which produce consistent results in presence of heteroskedastic error terms. Section 5 is devoted to the welfare analysis, in particular it investigates how much the heteroskedasticity-type-of-bias impacts the welfare gains from trade by substituting the resulting different measures of θ within the welfare equation. The final section summarizes my findings.

II. The EK model

In this section I outline the EK multi-country Ricardian model of trade by keeping the same notation as in the original paper.

EK extend the two-country Dornbusch et al. (1977) Ricardian model of trade with a continuum of goods $j \in [0, 1]$ to a world economy comprising $i = 1, 2, \dots, N$ countries. There's only one factor of production and the labor supply L_i differs from country to country; each worker supplies a unit of time inelastically in the domestic labor market and consumers purchase individual goods in amounts Q_i to maximize a CES utility function:

$$U = \left[\int_0^1 Q(j)^{\frac{(\sigma-1)}{\sigma}} dj \right]^{\frac{\sigma}{(1-\sigma)}}, \quad (1)$$

where the elasticity of substitution is $\sigma > 0$

What the Ricardian model of trade predicts is that countries should produce and export relatively more in industries in which they are relatively more productive. The source of comparative advantage lies in countries differential access to technology, so that efficiency varies across countries and industries. An industry of country i produces only one type of good $j \in [0, 1]$ with productivity $z_i(j)$. The country i 's productivity is a realization of a random variable (drawn independently for each j) from its specific Fréchet probability distribution $F_i(j) = \exp^{-T_i z^{-\theta}}$, where $\theta > 1$ and $T_i > 0$.

The parameter T_i (country state of technology) is a country specific parameter and it reflects country i 's absolute advantage. T_i governs the location of the distribution: the idea is that a bigger T_i indicates that a higher efficiency draw for any good j is more likely. The parameter θ governs comparative advantage and it is common across countries: it regulates heterogeneity across goods in countries relative efficiencies. A lower

value of θ , generating more variability across goods, means that comparative advantage exerts a stronger force trade against the resistance imposed by the geographic barriers d_{ni} .

EK treated the cost of a bundle of inputs as the same across commodities within a country (because inputs are mobile across activities within the same country and because activities do not differ in their input shares). They denote input cost in country i as c_i . Having drawn a particular productivity level, the cost of producing a unit of good j in country i is then $\frac{c_i}{z_i(j)}$, where c_i is the input cost in country i and it's defined as follows:

$$c_i = w_i^\beta p_i^{1-\beta}, \quad (2)$$

Since it's a Cobb-Douglas-type cost function β stands for the constant labor share; w_i is wage in country i while p_i is the overall price index of intermediates in country i .

The Samuelson iceberg assumption implies that shipping the good from country i to country n requires a per-unit iceberg trade cost of $d_{ni} > 1$ for $n \neq i$, with $d_{ii} = 1$. It is assumed that cross-border arbitrage forces effective geographic barriers to obey the triangle inequality: for any three countries i , k , and n , $d_{ni} \leq d_{nk}d_{ki}$.

Taking into account the Samuelson iceberg and the perfect competition assumptions, the price of a good imported from country i into country n is the marginal cost of production and delivery, which equals the unit production cost multiplied by the geographic barriers:

$$p_{ni}(j) = \left(\frac{w_i^\beta p_i^{1-\beta}}{z_i(j)} \right) d_{ni}, \quad (3)$$

Since the Ricardian assumptions imply that country i will search for the better deal around the world (pricing rule), the price of good j will be $p_n(j) = \min [p_{ni}(j); i = 1, \dots, N]$ i.e. the lowest across all countries i .

The pricing rule and the productivity distribution give the price index for every destination n :

$$p_n = \gamma \Phi_n^{-\frac{1}{\theta}}, \quad (4)$$

where $\Phi_n = \sum_{i=1}^N T_i (c_i d_{ni})^{-\theta}$ and $\gamma = [\Gamma(\frac{1+\theta-\sigma}{\theta})]^{-\frac{1}{1-\sigma}}$. Γ is the Gamma function and parameters are restricted such that $\theta > \sigma - 1$.

This price index expression has important implications regarding the role of geographic barriers in trade. First, in a zero gravity world Φ is constant for every country and the

law of one price applies: price index would depend on θ , γ and ϕ which are all constants. Second, positive geographic barriers $d_{ni} > 1$ is the only parameter which generates price differences across countries, leading to a deviation from purchase parity power and therefore creating incentives for bilateral trade.

By exploiting the properties of price distribution the fraction of goods that country n buys from country i is also the fraction of its expenditure on goods from country i . As EK point out, computing the fraction of income spent on imports from i , $\frac{X_{ni}}{X_n}$ can be shown to be equivalent to finding the probability that country i is the low-cost supplier to country n given the joint distribution of efficiency levels, prices, and trade costs for any good j . The expression for the share of expenditures that n spends on goods from i , or the trade share, is

$$\pi_{ni} = \frac{X_{ni}}{X_n} = T_i \left(\frac{(d_{ni}c_i)^{-\theta}}{\Phi_n} \right) = T_i \left(\frac{d_{ni}w_i^\beta p_i^{1-\beta} \gamma}{p_n} \right)^{-\theta}, \quad (5)$$

The trade share can be simplified to $\ln \pi_{ni} = S_i + S_n - \theta \ln \gamma - \theta \ln d_{ni}$, where S_i stands for the competitiveness of country i , which is function of technology, wages and prices: $S_i = \ln T_i - \beta \theta \ln w_i - \theta (1 - \beta) \ln p_i$.

As stated in EK, equation (5) is like a standard gravity equation which relates bilateral trade volumes to characteristics of trade partners and the geography between them.

However, instead of directly estimating this general gravity specification, EK provide a different version of trade equation where a transformed bilateral trade variable is regressed on technology and wages: they manipulate and substitute until the price of intermediates p_i disappears:²

$$\ln \left[\frac{X'_{ni}}{X'_{nn}} \right] = \ln \left[\frac{X_{ni}}{X_{nn}} \right] + \left(\frac{1-\beta}{\beta} \right) \ln \left[\left(\frac{\frac{X_n}{X_{nn}}}{\frac{X_i}{X_{ii}}} \right) \right] = S'_i - S'_n - \theta \ln d_{ni}, \quad (6)$$

where the competitiveness of country i reduces to $S'_i = \frac{1}{\beta} \ln T_i - \theta \ln w_i$

As can be observed, country i 's competitiveness is no longer a function of price of intermediaries as it was in the trade share expression. In addition, the wage coefficient gives exactly a measure of the elasticity of trade $\mu_w = \mu_t = -\theta$. In the trade share equation the wage elasticity is $\mu_w = -\beta\theta$ whereas the trade elasticity is $\mu_t = -\theta$. Thus, by calculating β the effect of wage variation on estimated exporter fixed effects gives an alternative source of identification for the same key parameter. Since $\beta = 0.2$, the trade elasticity will be 5 times the estimated wage coefficient.

²All the steps that lead to equation (6) are outlined in the Appendix.

III. Definitions, data and econometric specifications

III.A. Definitions

I construct trade shares X_{ni}/X_n following EK, Waugh (2010) and Simonovska and Waugh (2011). In the numerator is the aggregate value of manufactured goods that country i imports from country n in thousands of dollars. In the denominator is gross manufacturing production minus total manufactured exports (for the whole world) plus manufactured imports (for only the sample). Since bilateral trade flows are all positive in my samples, the lack of zeros poses no problem for the use of a gravity equation in log linear form.³

To construct home shares $\pi_{nn} = X_{nn}/X_n$ I followed the direct measure of the home share employed in Eaton and Kortum (2012).⁴ Country n 's imports from home X_{nn} are gross manufacturing production less gross manufacturing exports, while its total manufacturing expenditures X_n are gross manufacturing production less gross manufacturing exports, plus imports from the other countries of the sample. The home share is equivalent to $1 - \sum_{k \neq n}^N X_{ki}/X_n$, which is the expression commonly found in the literature.⁵

The EK's transformed version of bilateral trade in equation (6) differs significantly from the trade share expression. The EK dependent variable equals the normalized trade share by the importer home sales, plus the inverse of home trade share of country n , minus the inverse of home trade share of country i . While trade share depends negatively on country n 's imports, the EK's transformed version of bilateral trade is a positive function of the ratio between country n and country i 's imports: by keeping i 's imports fixed, higher country n 's imports have positive effect on the EK dependent variable. These different forms of bilateral trade which appear as dependent variable in the two econometric specifications will ultimately lead to different rankings of country's competitiveness.

The β parameter stands for the average labor share in gross manufacturing production in the sample and is calculated as follows:

$$\beta = \frac{\text{Wage} * \sum_n^N \text{Employment}_n}{\sum_n^N \text{Production}_n}, \quad (7)$$

³Other issues such as heteroskedasticity constitute a problem for the estimation of a gravity equation in log linear form as pointed out by Santos Silva and Tenreyro (2006). Appropriate estimation techniques such as Poisson PML will be utilised to deal with this issue.

⁴Eaton and Kortum (2012) show that π_{nn} is also the key measure to calculate welfare gains from trade along with trade elasticity θ , labor share β and the share of manufactures in the final spending α . All these measures with the exception of θ are directly observable from the data.

⁵See for instance Waugh (2010) or Simonovska and Waugh (2011)

where Wage is the average annual manufacturing salary per employee in the sample, while Employment_{*n*} is annual manufacturing employment in country *n*. The results are 0.21, 0.20 and 0.20 for the EK, the intermediate and the whole sample, respectively. All these values are in line with EK results.⁶ In order to test whether the measure of β is reproduced within the EK model by $\hat{\beta}$, manufacturing prices of intermediaries are regressed on manufacturing wages corrected for worker quality.⁷ From the EK model (equation (3) in section 2), the price of a unit of good *j* produced and purchased in country *i* reduces to: $\ln p_{ii}(j) = -\ln z_i(j) + \beta \ln w_i + (1 - \beta) \ln \bar{p}_i$, given that $d_{ii} = 1$. By dropping the price index and including technology into the error term, the effect of wages on prices $\hat{\beta}$ is 0.21 (se 0.02), very close to the true β .⁸

To calculate welfare gains from trade following Eaton and Kortum (2012) an additional parameter is needed. α is derived directly from the data and it stands for the manufacturing share of final spending. I calculate this parameter by solving for α according to the following expression from EK:

$$X_{nn} + IMP_n = (1 - \beta)(X_{nn} + EXP_n) + \alpha_n Y_n, \quad (8)$$

where IMP_n is total imports of country *n* in manufacturing, EXP_n stands for total exports of country *n* in manufacturing while Y_n is GDP of country *n*. The values of α_n for both samples are in line with the average manufacturing share calculated in EK. For the whole sample the mean of the manufacturing share is 0.12, while the correspondent value for the EK sample decreases to 0.10.

III.B. Data

My analysis uses data for manufacturing in 1997 for 27 OECD countries.⁹

■ **Trade data and proxies for geographic barriers.** Data on manufacturing production, total manufacturing exports and manufacturing imports are from the latest version of STAN database (2011).¹⁰ Since production and total exports in manufacturing are

⁶Eaton and Kortum (2002) and Eaton and Kortum (2012) obtained respectively 0.21 from a sample of 19 OECD countries, and 0.3 from a larger sample of 31 OECD countries.

⁷This simple regression is based on the intermediate sample of 25 OECD countries; this sample doesn't include New Zealand and Norway because of price data availability.

⁸The price index of country *i* here is indicated by \bar{p}_i instead of simply p_i . The purpose is to make clear the distinction between price index and $p_{ni}(j)$.

⁹The limit on the number of countries arises from the availability of data. 1997 has been chosen because GGDC data on relative manufacturing producer prices are available only for this year. Costinot et al. (2012) use the GGDC database as well and they chose 1997 as base year for exactly the same reason.

¹⁰For Australia I used estimates published on the previous version of STAN (2005). These estimates are based on ISIC Rev.3 official business survey/census statistics from OECD (SBS) Structural Statistics for Industry and Services database.

expressed in national currency, I converted them in current US dollars by using 1997 exchange rates (euro converted historical data for US dollars) from OECD database. Data on weighted distance and all the geographic barriers used in this paper namely common border, common language and RTA are from CEPII gravity database.¹¹

■ **Determinants of competitiveness.** As in EK I used annual compensation in total manufacturing in national currency from STAN database. Compensation of employees LABR encompasses wages and salaries of employees paid by producers as well as supplements such as contributions to social security, private pensions, health insurance, life insurance and similar schemes. Compensation of employees are then translated into US current dollars by using OECD exchange rates; in order to obtain the annual compensation per worker I divide the annual compensation by the number of employees in total manufacturing EMPE. For number of employees in total manufacturing I use STAN data for large part of my sample; for Australia, Belgium, Czech Republic, Estonia, Greece, Hungary, Ireland, Korea, Poland, Portugal, Slovakia, Slovenia and Sweden I use UNIDO data from the recent INDSTAT2 2012 database. In both INDSTAT2 and STAN databases data are collected using the 2-digit level ISIC Revision 3 industry classification. Compensation per worker data are then adjusted by worker quality, setting $w_i = (\text{comp}_i) \exp^{-gH_i}$, where h is average years of total schooling of population 15 and over in 1992 and g is the return to education. As in EK g is initially set to 0.06, which Bils and Klenow (2000) suggested as a conservative estimate. In order to test the impact on trade elasticity of a less conservative measure of return to education, wages and total employment will also be corrected using $g = 0.12$.

The trade share equation includes manufacturing relative prices for intermediates; data on manufacturing (total manufacturing, excluding electrical) producer relative prices (PPP, in local currency per US dollars) for intermediates are from GGDC productivity database.¹² The *manufacturing* category here is again defined according to the ISIC revision 3 industry classification. The PPP indicates the relative price in a country relative to the US: once converted, a PPP higher than 1 indicates a higher price in that country compared to US. I converted the PPPs in current US dollars by using 1997 exchange rates (euro converted historical data for US dollars) from OECD database. The exceptions are Slovakia and Estonia: these two countries adopted Euro in 2009 and 2011, while Timmer-Inklaar paper has been published earlier in 2008. Thus, for Slovakia and Estonia local currency units for US dollars exchange rates from World

¹¹Weighted distance calculates the distance between two countries based on bilateral distances between the biggest cities of those two countries: those inter-city distances are weighted by the share of the city in the overall country's population. The CEPII gravity database includes data on distance between n and i based on the following formula from Head and Mayer (2002): $d_{ni} = \left(\sum_{k \in n} \frac{\text{pop}_k}{\text{pop}_n} \right) * \left(\sum_{l \in i} \frac{\text{pop}_l}{\text{pop}_i} \right) * d_{kl}$, where pop_k stands for the population of agglomeration k belonging to country n while pop_l is the population of agglomeration l belonging to country i .

¹²Inklaar, R. and Timmer, M.P. (2008). 'GGDC Productivity Level Database: International Comparisons of Output, Inputs and Productivity at the Industry Level' Groningen Growth and Development Centre Research Memorandum GD-104, Groningen: University of Groningen.

Bank have been used.

The PPP for intermediates for country i is given by:

$PPP_{II} = \frac{PPP_i^{II}}{PPP_{US}^{II}}$, where II is the sum of sectoral energy, material and services inputs at current prices i.e. $II = IIE + IIM + IIS$

Total labour force and the inverse of population density are the instruments for wage costs. The inverse of population density is obtained as the inverse of the ratio of country's total labour force over land area. Total labour force data in thousands of workers are obtained from the annual labor force statistics OECD database, with the exception of Estonia, which is from the UN database. Like wages, total employment is corrected for education, setting $L_i = (\text{work}_i) \exp^{gH_i}$.

Average years of schooling and R&D expenditures in current US dollars are the proxies for technology. Average years of schooling of adults (aged 15+) for 1992 are obtained through the linear interpolation of Barro and Lee (2010) data. Since Barro Lee data are available 5 years in 5 years, I linearly interpolated 1990 and 1995 in order to get 1992 estimates. All country's R&D shares of GDP are from the CANA database, a panel dataset for cross-country analyses of national systems;¹³ the only exception is Korea, which is from World Bank because not available in CANA. GDP data in billions of current US dollars are from IMF.¹⁴

■ **1990's EK model replication.** In section 4 I replicate EK empirical analysis for 1990. This exercise is useful mainly for two reasons. First, since EK used different data sources for instrumental variables, geographic barriers and technology, it's relevant to check whether my data lead to estimates which are consistent with EK results. Second, I show that using a different dataset for average years of education has a quite significant impact on the measure of trade elasticity. For this analysis I use 1990 manufacturing exports, production, wages and employment from the latest STAN version, while manufacturing bilateral trade data are from an older version of STAN (2002). Geographic variables are again from CEPII gravity database. Data for 1985 education are from Barro and Lee (2010) and Cohen and Soto (2001), whereas 1990 data on R&D expenditures and GDP are again from the same sources used for the 1997 analysis. Cohen and Soto (2001) estimates for 1985 are obtained through linear interpolation.¹⁵

III.C. Econometric specifications

■ **Two-step approach.** In the first stage a transformed version of bilateral trade is regressed on measures of bilateral trade costs (geographic barriers), importer and ex-

¹³Available at <http://english.nupi.no/Activities/Projects/CANA>

¹⁴Available at <http://www.imf.org/external/data.htm>

¹⁵Cohen-Soto database is available at <http://soto.iae-csic.org/Data.htm>

porter fixed effects. The estimated exporter fixed effects obtained in the first stage are then regressed on two proxies for technology (R&D expenditures and human capital) and wages corrected for worker quality.

From equation (6), the first stage regression becomes:

$$\ln \left[\frac{X'_{ni}}{X'_{nm}} \right] = S'_i - S'_n - \theta d_{ni} - \theta \text{lang}_{ni} - \theta \text{contig}_{ni} - \theta \text{RTA}_{ni} + \theta \delta_{ni}$$

Where for every $i \neq n$, $\ln \bar{d}_{ni} = \theta d_{ni} - \theta \text{lang}_{ni} - \theta \text{contig}_{ni} - \theta \text{RTA}_{ni} + \theta \delta_{ni}$.¹⁶ S'_i and S'_n are respectively the exporter and importer country fixed effects; d_{ni} is the weighted distance between country i and country j ; lang_{ni} is the effect of importer and exporter sharing a language, while contig_{ni} is the effect of i and n sharing a border. RTA_{ni} is a common free trade area effect and δ_{ni} is the residual effect on trade which is assumed orthogonal to all regressors.

In order to capture potential reciprocity in geographic barriers, the error term is assumed to be consisting of two components as in EK, where $\delta_{ni} = (\delta_{ni}^1 + \delta_{ni}^2)$. The first term is country specific and it affects trade *one-way*, while the second term is country pair specific and affects trade *two-way*.

Santos Silva and Tenreyro (2006) argue that OLS with log of trade as dependent variable becomes an inconsistent estimator in the presence of Poisson-type heteroskedasticity. Santos Silva and Tenreyro (2006) suggested Poisson pseudo-MLE as a valid alternative to linear-in-logs OLS for multiplicative models like the gravity equation. The Poisson PML (PPML) estimator guarantees consistent estimates regardless of the distribution of the error term, as long as:

$$E[X_{ni}|z_{ni}] = \exp(z'_{ni}v).$$

where X_{ni} is bilateral trade, z'_{ni} is the transpose of a vector of the trade cost variables and v is the correspondent vector of coefficients.

The Poisson PML estimator has often been used for count data models. Santos Silva and Tenreyro (2006) estimated a gravity model with Poisson PML using bilateral trade flows measured in levels as dependent variable. However, as pointed out by Gourieroux et al. (1984), the PML method with Poisson family may be applied even if the dependent variable is any real number: as long as the trade flow is greater or equal than zero, the estimator based on the Poisson likelihood function is consistent. Since both the trade share X_{ni}/X_n and the transformed version of bilateral trade X'_{ni}/X'_{nm} are strictly positive because $X_{ni} > 0$, both specifications have the requisites to be estimated consistently with Poisson PML.

¹⁶In section 2 I indicate geographic barriers as d_{ni} ; here I used \bar{d}_{ni} to clarify the distinction between weighted distance and the parameter which includes distance and all the geographic dummies.

After conducting a Monte Carlo simulation, Head and Mayer (2013) argue that Poisson PML should not replace OLS as the workhorse for gravity equation; alternatively, they suggest to use Poisson PML as part of a robustness-exploring ensemble which includes OLS and Gamma PML.¹⁷ Following Head and Mayer (2013) I test the reliability of the first-stage OLS estimates by contrasting OLS with Poisson PML results. As noted by Head and Mayer (2013), if there's a significant discrepancy between Poisson and OLS coefficients, then it is reasonable to conclude that heteroskedasticity is an issue and the OLS estimates are unreliable. In Anderson and Yotov (2010a), Helpman et al. (2008) and Santos Silva and Tenreyro (2006) the comparison between the Poisson PML and the OLS gravity estimates reveal that the latter are biased upward.

In the gravity literature importer and exporter fixed effects have mainly been seen as vital *controls* needed to obtain consistent estimates of the trade cost variables but not particularly useful in their own right. Santos Silva and Tenreyro (2006), Head and Mayer (2013) and Eaton et al. (2012) contrast OLS with PPML coefficients by comparing a few key gravity variables like distance, RTA and the usual geographic dummies without showing the effects of heteroskedasticity-type-of-bias on importer and exporter fixed effects. Given the importance of these coefficients for the estimation of trade cost elasticity through the EK two-step competitiveness equation methodology, the comparison between OLS and Poisson PML estimates will be extended also to exporter fixed effects.

From equation (6) the second stage regression becomes:

$$\hat{S}_i' = \alpha_0 + \alpha_R \ln R\&D_i + \alpha_H \ln H_i - \theta \ln w_i + u_i$$

where $R\&D_i$ is country i 's R&D expenditure, H_i is the average years of education, w_i is country i wages adjusted for education and u_i is the error term assumed orthogonal to all regressors. In this specification the elasticity of trade θ coincides with the effect of wages on competitiveness.

■ **One-step approach.** By plugging the determinants of S_i' into the EK bilateral trade equation, I obtain the following one-step competitiveness specification:

$$\ln \left[\frac{X_{ni}'}{X_m} \right] = \alpha_0 + \alpha_R \ln R\&D_i + \alpha_H \ln H_i - \theta \ln w_i - S_n - \theta \ln d_{ni} \\ - \theta \ln g_{ni} - \theta \ln contig_{ni} - \theta RTA_{ni} + \delta_{ni}^1 + \delta_{ni}^2 + u_i$$

¹⁷In a second simulation Head and Mayer (2013) reveal that Gamma PML does not perform well in the presence constant variance to mean ratio (CVMR) error term and is even biased under the log-normal assumption. They conclude that the performance of this estimator worsens probably because of the presence of zeros. However, as opposed to Gamma PML, Poisson PML with country fixed effects is showed to be unbiased with CVMR errors in both Head and Mayer (2013) simulations; given these results, in this analysis PPML is the only estimator which will be compared to OLS.

Head and Mayer (2013) identified in the literature 744 gravity based estimates of trade elasticity that have been obtained for the full sample of 32 papers. Many of these coefficients have been estimated through a one-step procedure. In EK, for instance, two of the three methodologies implemented to obtain an estimate of trade elasticity are one-step.

However, one-step and two-step methodologies are not equivalent. According to the literature, there may be substantial differences between one-step and two-step procedures: differences involving both the magnitude as well as the standard errors of the coefficients.^{18,19}

Baker and Fortin (2001) showed that the one-step methodology may lead to biases in the coefficients if and only if the second-stage error term u_i is not orthogonal to the one-step regressors, namely geographic barriers, exporter and importer fixed effects.²⁰ Otherwise, all else being equal, the two procedures should lead to similar estimates under the assumption that u_i is truly a random effect. In the equation above, the residual u_i captures the impact on country i 's competitiveness of variables other than wages and technology: this effect in the one-step procedure should be incorporated in the error component that affects trade one way. Thus, if the assumption of δ_{ni} consisting of two components both orthogonal to the first stage regressors is correct, u_i is also orthogonal to the one step regressors and the two procedures should lead to similar estimates.

Since country characteristics are likely to be correlated within groups, the estimated coefficients may show a much lower variance in the one-step procedure when using heteroskedasticity consistent White robust standard errors. Moulton (1986) argues that a possible cause for relatively lower standard errors in the one-step procedure might be a source of downward bias due to the correlation of the individual error terms within groups; this may lead to serious mistakes in statistical inference. This bias derives from using grouped data in an individual level regression where groups are not allowed to be treated as fixed parameters. To quantify the magnitude of this bias, Macpherson and Hirsch (1995) found that the single step estimation produced coefficients with standard errors ten times lower compared to the standard errors obtained through the two-step procedure. To correct for the one-step Moulton bias, I use standard errors clustered by country i .

The number of clusters is crucial to establish whether or not the standard cluster adjustment is reliable. Angrist and Pischke (2009) argue that with few clusters there's a tendency to underestimate the intraclass correlation in the Moulton problem. However, there's not a specific number of clusters considered as a threshold which separates a

¹⁸See for example Macpherson and Hirsch (1995) or Baker and Fortin (2001).

¹⁹The comparison between one-step and two-step procedure will be based solely on the OLS estimates.

²⁰The assumption I made for the competitiveness regression implies that u_i is orthogonal to the competitiveness determinants

reliable from an unreliable standard cluster adjustment. Angrist and Pischke (2009) propose 42. The same authors seem a bit skeptical about this number, since the literature provides examples where clustered standard errors are reasonably good even in a scenario with 10 groups.

■ **Trade share regression.** From equation (5) I obtain the following one-step specification:

$$\ln\left(\frac{X_{ni}}{X_n}\right) = \alpha_0 + \alpha_R \ln R\&D_i + \alpha_H \ln H_i - \theta\beta \ln w_i - \theta(1 - \beta) \ln p_i \\ + S_n - \theta \ln d_{ni} - \theta \ln g_{ni} - \theta \ln contig_{ni} - \theta RTA_{ni} + \delta_{ni}^1 + \delta_{ni}^2 + u_i$$

where $\theta \ln \gamma$ is included into the error term. The trade share two-step specification becomes $\hat{S}_i = \alpha_0 + \alpha_R \ln R\&D_i + \alpha_H \ln H_i - \theta\beta \ln w_i - \theta(1 - \beta) \ln p_i + u_i$

To better compare the trade share results with the estimates from the EK model, in the following trade share regressions β is substituted with the actual value of the labour share for each sample. This allows to easily confront the trade elasticity coefficients between these two different specifications, since we are back to $\mu_t = -\theta$ as in the EK original competitiveness equation. For the whole sample, the second stage regression reduces to $\hat{S}_i = \alpha_0 + \alpha_R \ln R\&D_i + \alpha_H \ln H_i - \theta 0.2 \ln w_i - \theta 0.8 \ln p_i + u_i$. β takes the value of 0.21 in the EK sample.

Applying the Stata Poisson command to a gravity model which includes the trade share π_{ni} as dependent variable and country specific fixed effects, provides the Multinomial PML estimator, as proved by Sebastian Sotelo in unpublished notes. Eaton et al. (2012) argue that Multinomial PML is the best estimator in models with a finite number of buyers and sellers, where the EK continuum assumption is abandoned.

Since data on manufacturing relative prices are not available for Norway and New Zealand, the trade share regression is estimated initially only for an intermediate sample of 25 OECD countries. Once the relative price variable is dropped because proved to be redundant, the trade share is estimated for the other two samples as well. Poisson PML is used as a robustness check for the OLS estimations in the first stage, and the resulting exporter fixed effects are used as dependent variables in the second stage.

IV. Results

Table 1 reports the second stage results of the EK empirical analysis replication for 1990. Since EK in their original paper use different data sources for instrumental

variables, geographic barriers and technology, it's relevant to check whether the data utilised in this analysis lead to estimates which are consistent with the EK results.²¹

The estimated exporter fixed effects are obtained from a first stage regression whose structure is very similar to the EK specification: the estimations are from the same sample of 19 OECD countries, and the same bloc dummies (EFTA and EC) are included to measure the RTA effect. In addition, I calculated $\beta = 0.21$, which is exactly the EK result. In contrast to the original EK specification, the first stage regression is estimated using OLS with robust standard errors, while distance is measured as the log of weighted distance as commonly found in the literature.²² Table 7 in the Appendix reports the first-stage estimates. In line with EK results the estimates show that Japan is the most competitive country in 1990, while Belgium is at the same time the most open and the least competitive country of the sample. All the gravity controls have the expected sign with the exception of common border.

²¹EK utilized average years of schooling for 1985 from Kyriacou (1991), stocks of research for each country from Coe and Helpman (1995) and aggregate workforce, which is used as instrument for wages, from Summers and Heston (1991). Kyriacou (1991) estimates average years of schooling in the labor force as an index of human capital stock. As for R&D data, Coe and Helpman (1995) estimate stocks of research using the perpetual inventory method (assuming a depreciation rate of five percent) to add up real R&D investment by business enterprises. In Summers and Heston (1991) the labor force participation rate and total workforce, are given implicitly by the values of gross domestic product per capita and per worker.

²²EK estimate the regression by generalized least squares (GLS). They also divide distance in 6 intervals, all included in their first stage specification (p.1762).

The \hat{S}_i' are then regressed on two proxies for technology (R&D expenditures and average years of education) and wages corrected for worker quality. The second-step regression is estimated twice, using different database for education: first Barro and Lee (2010), then Cohen and Soto (2001). Since human capital is used to correct both wages and labour force for worker quality, and it also appears as a proxy for technology, a different database for education could lead to substantial differences in the measure of the elasticity of trade.²³ The structure of the second stage specification is maintained identical to the original EK competitiveness equation: the inverse of the average years of schooling is used as a proxy for human capital and the same EK instruments for wages have been used.

As can be observed from Table 1, the elasticity of trade obtained through 2SLS ranges between 4.03 and 3.40 which I view as reassuring, since both estimates are quite close to 3.60. Using a different database for education affects the estimation of the elasticity of trade: the difference between the two 2SLS estimates is around 0.6. Finally, as in EK, the effect of education on country i competitiveness is not statistically significant and only Cohen and Soto (2001) data give the expected sign; as for R&D, both effects are similar in magnitude to the EK results.²⁴

²³This kind of experiment couldn't be conducted for the whole sample of 27 countries for 1997, since some of the data on education needed for the comparison are not available in Cohen-Soto database.

²⁴The first stage results obtained using OLS with robust standard errors are almost identical to the

In order to test for the presence of heteroskedasticity-type-of-bias in the 1997 OLS estimates, the first stage has been estimated using OLS as well as Poisson PML. The results are reported in Table 8 in the Appendix. As opposed to the 1990 analysis, in the 1997 specification RTA effect is captured by a common RTA dummy.²⁵ For both samples, there's a significant discrepancy between OLS and Poisson PML estimates, which indicates a bias in the OLS results due to heteroskedasticity. The direction of the bias is not as clear as in Anderson and Yotov (2010a), Helpman et al. (2008) and Santos Silva and Tenreyro (2006), where there's a tendency for OLS coefficients to be biased upward. The discrepancy between OLS and PPML results showed in Table 8 is particularly evident by looking at the \hat{S}_i' coefficients. In line with Anderson and Yotov (2010b) I obtain almost perfect correlation between OLS and PPML \hat{S}_i' gravity estimates: for both samples the correlation coefficient is 0.99. However, since this bias affects the mean (and the variance) of the second stage dependent variable, \hat{S}_i' , OLS and PPML exporter fixed effect coefficients cannot be used interchangeably for the two-step estimation of θ . Therefore, despite the high correlation between OLS and PPML, the impact of wage on competitiveness will be affected by heteroskedasticity-type-of-bias of the first stage \hat{S}_i' coefficients. The question is how much.

Table 2 reports the second stage results for 1997. The estimates are obtained using 2SLS. As Head and Mayer (2013) pointed out, wages are likely to be simultaneously determined with trade patterns; thus, in order to correct for endogeneity I instrument for wages using 2SLS. I use labour supply instruments for wages as in EK: total labor force and the inverse of population density which proxy respectively for labour supply and for productivity outside manufacturing. As in Costinot et al. (2012), EK and Erkel-Rousse and Mirza (2002), the estimated effect of the proxy for exporter competitiveness is larger when instrumenting using OLS: trade elasticity increases from 5.09 (se 3.02) to 6.32 (se 3.39) for the EK sample, whereas θ goes from 1.34 (se 1.07) to 2.01 (se 1.58) for the whole sample. This trend applies to the regression results obtained with parameters from a PPML first stage: θ increases from 4.00 (se 3.18) to 4.99 (se 3.46) for the EK sample, while the same parameter goes from 1.37 (se 1.17) to 2.50 (se 1.65) for the whole sample.

The evidence that emerges from these first two tables indicate a sort of instability of the measure of trade elasticity: this coefficient varies dramatically both with sample size and over time. For the same EK sample, the difference between the 1997 estimate of θ and the correspondent measure for 1990 is around 2.92, whereas the discrepancy between the same coefficient for 1997 between EK and the whole sample is 4.32. This

ones obtained using WLS, which is just a special case of the more general estimating technique GLS. As a consequence, both WLS and OLS fixed effects coefficients lead to identical measures of θ . These results are available upon request.

²⁵ R^2 for Poisson PML is calculated using the (squared) correlation between the observed response and the predicted response. As Zheng and Agresti (2000) pointed out, the correlation between the response and the fitted response can be considered as a general measure of predictive power for generalized linear models (GLMs).

huge variability is in line with the findings of Head and Mayer (2013). Head and Mayer (2013) identified in the literature 744 trade elasticity coefficients obtained for the full sample of 32 papers: they show that the mean of the estimates dealing with the multilateral resistance terms through country fixed effects is 4.12, but the standard deviation is twice as large. Finally, as expected, the discrepancy between OLS and PPML coefficients in the first stage significantly affects the resulting measure of θ obtained in the second stage: the difference between PPML and OLS wage elasticities is around 1.30 for the EK sample and 0.50 for the whole sample.

Table 3: One-step estimations

	OLS	2SLS	OLS	2SLS

Notes: standard errors clustered by exporter in parentheses.

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

According to the recent estimates of Barro and Lee (2010), less advanced economies showed low returns to education, whereas an additional year of schooling in advanced countries has an impact on output of 0.13.²⁶ Since the empirical analysis is based on samples of OECD countries, it's interesting to test the impact on trade elasticity of a less conservative measure of g . As it turned out, doubling the measure of the return to education has a quite significant impact on the wage effect only for the EK sample. Correcting wages and total labour force with $g = 0.12$ instead of $g = 0.06$, reduces the measure of θ by 0.63, and 0.05 for the EK and the whole sample, respectively.²⁷

²⁶Barro-Lee estimates of rates of return to education significantly vary across regions. The estimates are the highest at 13.3% for the group of advanced countries. In contrast, the returns are around 6.5% in less advanced areas such as Sub-Saharan Africa and Latin America.

²⁷These numbers refer to the 2SLS from OLS first stage estimations. The correspondent measures from Poisson PMLE are 0.51 and 0.06.

Before proceeding to the one-step analysis, two important remarks about Table 2 results are worth mentioning.

- The sign of human capital is the opposite of what the theory predicts. EK obtained the correct sign for education, but the resulting effect was not statistically significant.²⁸
- The standard errors of the competitiveness regression coefficients are relatively high (with the exception of R&D); this leads to three 2SLS θ coefficients statistically insignificant.

Table 4: Ratios of standard errors

	19c	27c	19c	27c
$\ln Wages_i$	3.42	4.17	3.31	5.29
$\ln R\&D_i$	3.45	3.95	3.35	5.20
$1/H_i$	2.32	4.03	3.10	5.43
Constant	3.02	3.24	2.85	5.00

Notes: columns 1 and 2 report clustered by exporter *se/robust se*

Notes: columns 3 and 4 report two-step *se/robust se*

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

Table 3 shows the one-step results. The 2SLS technique is employed using the same instruments for wages as in the two-step approach. As it emerges from the estimates, the measure of θ is again larger when instrumenting. The one-step results seem partly consistent with the assumption of orthogonality of δ_{ni} , since for the whole sample the 2SLS estimation of θ is very close in magnitude to the correspondent two-step measure reported in Table 2. The difference is only around 0.13. However, the measure of θ obtained from the smaller EK sample shows a discrepancy of 0.88, which indicates a possible bias in the one-step estimation.

To correct for the one-step Moulton bias, I use standard errors clustered by country i . The first two columns of Table 4 reports the ratio between standard errors clustered by exporter and White robust standard errors for the one-step procedure. The ratios indicate that on average standard errors are between three and four times higher when clustered by exporter. The ratios between two-step and one-step White robust standard errors are showed in columns 3 and 4: the evidence indicates that the ratios are substantially lower than the correspondent measures found in Macpherson and Hirsch (1995).

²⁸In EK the effect of (the inverse of) education on country i 's competitiveness is -22.7 (se 21.3).

As expected, the one-step standard errors clustered by exporter are closer to the ones obtained with the two-step procedure. This is true especially for the EK sample, as the first and third columns of Table 4 show very similar ratios for all coefficients. The ratios reported in the second and fourth columns show a larger discrepancy. This result is a bit surprising, since according to Angrist and Pischke (2009) a higher number of clusters should imply a reduction in the Moulton bias because of a lower intraclass correlation. My results seem to go in the opposite direction.

Table 5: Trade share 2SLS - 25 countries

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

Given the potential bias in the estimate of θ obtained from the EK sample and the relatively low number of clusters which cast doubts on the reliability of the standard cluster adjustment, the two-step estimations of trade cost elasticity are preferred.

In order to estimate the trade share regression a smaller sample of 25 countries has been used, since data on manufacturing relative prices are not available for Norway and New Zealand. Table 5 reports the two-step 2SLS coefficients.²⁹The dependent variable is exporter fixed effects \hat{S}_i obtained from a first stage regression estimated both using OLS

²⁹The first stage is estimated using OLS with robust standard errors and Poisson PML. The estimates are available upon request.

and Poisson PML. Wages and R&D are the only statistically significant coefficients among the determinants of competitiveness. By using the same instruments for wages, the dependent variable obtained from Poisson PML leads to a wage elasticity of 0.78. In this specification the wage elasticity is $\mu_w = -\beta\theta$, with $\beta = 0.2$ the trade elasticity is 5 times the estimated wage effect on trade. Thus, as reported in column 1, this leads to a measure of $\theta = 3.91$. The correspondent two-step measure of θ from the OLS first stage is 2.89 and it's not statistically significant.

However, the coefficients of the exporter relative price on competitiveness have the wrong sign and both the effects are not statistically significant. This is not surprising, since most of the impact of p_i is likely to be captured by the wage parameter, which makes the price variable redundant. By running the same regression without controlling for prices the two-step measure of θ obtained from the OLS first stage is 2.58, statistically significant at 5% level, whereas the correspondent parameter from the Poisson PML first stage is 3.55, statistically significant at 1%.

Since the price variable is proved to be redundant in this model, it's now possible to compare the trade share estimations of θ with the measures of trade elasticity obtained previously from the EK benchmark model, for both the EK and the whole sample. Table 9 reports the first-stage regression results of the trade share specification. As in the EK's first stage, I check for the presence of Santos Silva and Tenreyro type of bias in the OLS estimates due to heteroskedasticity, by comparing OLS with Poisson PML.

The results reported in Table 8 indicate the presence of an upward bias of the OLS coefficients, particularly evident in the exporter fixed effects estimates \hat{S}_i . The correlation between OLS and PPML exporter fixed effects coefficients is still very high, around 0.98 for both samples. Again, these correlation coefficients do not provide any information on the magnitude of θ obtained in the second step, since highly correlated set of coefficients which are almost equivalent in relative terms may produce different measures of trade cost elasticity.

What emerges from the comparison between \hat{S}_i and \hat{S}_i' is the relatively low level of correlation between the two sets of coefficients across both econometric techniques: the correlation coefficient drops to 0.64 and 0.69 for the EK sample, and to 0.78 and 0.76 for the whole sample.³⁰ These relatively low levels of correlation are coupled with significant differences in the variance and the mean between the two set of coefficients for both samples.³¹ In addition, the two different specifications lead to different rankings of country's competitiveness: since the two specifications have different forms of bilateral trade as dependent variable, the measure of country's competitiveness varies accordingly. For instance, by comparing column 1 results between Table 8 and Table 9, Belgium goes from being the least competitive country in the sample, importing almost

³⁰For each sample the first and the second coefficients denote the correlation between OLS and PPML set of coefficients, respectively.

³¹Standard deviation and mean results are available upon request.

two times less than Australia in manufacturing [$\exp(-10.868)-1 = 0.99$], to import only 30.7% less than Australia [$\exp(-0.368)-1 = 0.307$].

Table 6 shows the second stage trade share results. The table reports the two-step coefficients for the EK and the whole sample. The dependent variables of columns 2 and 4 are obtained using Poisson PML, whereas the \hat{S}_i of columns 1 and 3 are from OLS. Again, the discrepancy between OLS and Poisson PML coefficients in the first stage significantly affects the resulting measure of θ obtained in the second stage. However, the trade share estimates lead to an higher difference in absolute value between Poisson PML and OLS trade elasticities compared to the EK benchmark results. The discrepancy is around 2.63 for the EK sample and 1.23 for the whole sample. The measures of trade cost elasticity estimated from the whole sample are very distant from the mean of θ coefficients of 4.12 reported in Head and Mayer (2013).

Table 6: Trade share 2SLS

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

For the EK sample the inverse of education has the right sign as in EK. However, for the whole sample the sign is again reverted. One of the possible explanations is that some of the countries that trade less in the enlarged sample are those characterized by high levels of average years of education, especially former socialist economies such as Estonia, Slovenia, Slovakia, Czech Republic and Hungary.

The trade share estimates of trade cost elasticity can be considered as a sort of additional robustness check for the first stage OLS results. The differences in the wage

elasticity coefficients between trade share and EK specification indicate that OLS provides biased estimates of country's competitiveness. On the contrary, the gravity model estimated with Poisson PML lead to very similar measures of θ across specifications. As can be observed from Table 6, the S_i' estimated with OLS yields statistically insignificant trade elasticity parameters of 2.28 and 0.63; these values are 4.31 and 1.38 lower than the correspondent EK benchmark results of Table 6. On the contrary, the first stage estimation of S_i from Poisson PML leads to statistically significant measures of θ of 4.91 and 1.86. These estimates are only 0.08 and 0.64 lower than the correspondent results obtained from the EK benchmark model.

These findings confirm that heteroskedasticity-type-of-bias is an issue and therefore the estimation of trade elasticity through the two-step competitiveness equation can be considered reliable if S_i are estimated with econometric techniques, such as Poisson PML, which produce consistent results in presence of heteroskedastic error terms.

V. *Welfare analysis*

As Eaton and Kortum (2012) pointed out, anything that lowers a country's cost of serving a market, means more purchases are shifted there. How much depends on θ . Given a change in trade costs, the higher θ , the more similar are the technologies (and costs) across goods for all countries, the bigger the shift in trade shares. Eaton and Kortum (2012) provides a simple framework which allows to interpret and calculate how a shift in trade elasticity translates into welfare gains from trade. Following Eaton and Kortum (2012) the gains from trade of country n are expressed as follows:

$$G_n = 100 * \left[\pi_{nn}^{(-\alpha_n/\theta\beta)} - 1 \right], \quad (9)$$

where π_{nn} is the home share of country n , α_n is the manufacturing share of country n and β is the average labor share calculated for each sample. Eaton and Kortum (2012) argue that $\alpha/\theta\beta$ is the elasticity which translates a smaller home share into larger gains from trade. The benefits from trade are limited to the manufacturing sector, but since manufactures represents a major input into the production of manufactures there are indirect benefits of trade in lowering input costs. These two opposite effects are taken into account in equation (9) by including the parameters α and β .³²

As the previous section clearly indicates, the bias in the first stage OLS results due to heteroskedasticity significantly affects the measure of θ . Table 10 in the Appendix shows the implications of this bias in the calculation of the welfare gains from trade. The home share π_{nn} , β and α are all calculated directly from the data. While Eaton and Kortum (2012) and EK impose a common manufacturing demand share α across

³²In Arkolakis et al. (2012) the same expression for the elasticity which translates a smaller home share into larger gains from trade is $1/\theta$. They show that this expression generalizes to a wide class of models

countries, the counterfactuals of Table 10 are performed using α_n ; the values of the manufacturing share are calculated according to equation (8) and are reported in the first column of Table 11.

Column 1 of Table 10 reports the home share for all the 19 countries of the EK sample. Since the trade share measures of θ from the EK sample are closer in magnitude to the average of 4.12 reported in Head and Mayer (2013), the values of trade cost elasticity used to calculate welfare gains are taken from the estimates of Table 6.³³ Column 2 shows the values of G_n by using a measure of $\theta = 2.28$, whereas column 3 reports the correspondent values of $G_n(p)$ obtained utilising the unbiased estimate of $\theta = 4.91$. Lastly, column 4 reports the welfare gains from trade by using $\theta = 3.60$, the 1990 Eaton and Kortum (2002) benchmark estimated using the competitiveness equation methodology.

In general, gains from trade are substantial, especially for small economies. Countries with a relatively small size such as Belgium, Austria and Portugal show large gains. As expected, the difference in the measure of θ due to the heteroskedasticity-type-of-bias significantly affects G_n . A decrease of 2.63 in the magnitude of trade elasticity produces on average an increase of 122% in terms of welfare gains; in addition, by comparing the results of column 4 to the gains obtained using the 1990 EK benchmark $\theta = 3.60$, a decrease of 1.31 of the same key parameter gives on average an increase of 38%.

Lastly, as it emerges from Table 11, using a common value for manufacturing share has important implications for welfare analysis. Since α_n varies by country, utilising common values such as the sample mean of the manufacturing share for all countries creates distortion in the calculation of G_n . Column 2 reports the change in welfare gains from trade between $G_n(p)$ and a measure of benefits obtained using a common larger manufacturing share of 0.2 as in Eaton and Kortum (2012) and Dekle et al. (2007). The results indicate that, all else being equal, imposing a larger α for all n tends to significantly overestimate the benefits from trade, especially for those countries with a very small manufacturing share of final spending. In particular, Belgium, Finland and Sweden increase their welfare gains from trade by 463%, 550% and 305%, respectively.

By the same token, using the sample mean α as a common manufacturing share for all countries, penalizes those economies with relatively high α_n and overestimates welfare gains for countries with a lower share. As it is reported in column 3, the country with the highest manufacturing share in the sample, Portugal, decreases its benefits from trade by 45%, while Belgium, Finland and Sweden preserve very large gains. On

³³In addition, as opposed to the correspondent coefficients obtained from the EK model, the trade share θ coefficient from PPML is statistically significant at 1% level. The coefficients obtained from the whole sample in Table 6 are too low in absolute value with respect to the value of 4.12 reported in Head and Mayer (2013).

the other hand, the two countries with the lowest manufacturing share in the sample, Belgium and Finland, increase their welfare gains by 153% and 232%, respectively.

VI. Conclusions

What emerges from the empirical analysis is the extreme variability of the trade elasticity parameter obtained from the EK competitiveness equation: the 1997 θ coefficients are all quite distant from the 1990 Eaton and Kortum (2002) benchmark of 3.60 and they vary dramatically with the sample size. These results are confirmed by the one-step estimations.

As opposed to large part of the gravity literature which sees importer and exporter fixed effects only as vital controls needed to obtain consistent estimates of the trade cost variables, this paper provides evidence on the unbiasedness of exporter fixed effects as an essential requisite to obtain reliable estimates of trade cost elasticity through the EK two-step competitiveness equation methodology.

The trade share results provide an additional robustness check for the first stage OLS estimates. The statistics confirm that the estimation of trade cost elasticity can be considered reliable if S_i are estimated with econometric techniques, such as Poisson PML, which produce consistent results in presence of heteroskedastic error terms.

Given the key role of trade cost elasticity in the calculation of welfare gains from trade, the resulting variability of θ poses a problem of identification of these benefits. This issue has important implications for policy making. By keeping fixed the home shares, a fall of 1.31 in the magnitude of trade elasticity due to heteroskedasticity-type-of-bias produces on average an increase in terms of welfare of 38%. Similar distortions in the calculation of benefits from trade arise by utilising a common manufacturing share parameter for all countries. The statistics indicate that using the sample mean of the manufacturing share as a common parameter instead of the actual value of α_n , substantially overestimates welfare gains for countries with a lower share and severely penalizes those economies with a relatively high demand for final manufactures.

VII. Appendix

In what follows I illustrate the steps which lead to equation (6)

The starting point is the trade share expression (equation (5)):

$$\frac{X_{ni}}{X_n} = \pi_{ni} = T_i \left(\frac{d_{ni} w_i^\beta p_i^{1-\beta} \gamma}{p_n} \right)^{-\theta}$$

EK use this expression as it applies to home sales for country n :

$$\frac{X_{nn}}{X_n} = T_n \left(\frac{w_n^\beta p_n^{1-\beta} \gamma}{p_n} \right)^{-\theta} = T_n \left(\gamma w_n^\beta p_n^{-\beta} \right)^{-\theta}$$

and country i :

$$\frac{X_{ii}}{X_i} = T_i \left(\frac{w_i^\beta p_i^{1-\beta} \gamma}{p_i} \right)^{-\theta} = T_i \left(\gamma w_i^\beta p_i^{-\beta} \right)^{-\theta}$$

where $d_{nn} = d_{ii} = 1$

The ratio leads to the following expression:

$$\frac{\frac{X_{ii}}{X_i}}{\frac{X_{nn}}{X_n}} = \frac{T_i \left(\gamma w_i^\beta p_i^{-\beta} \right)^{-\theta}}{T_n \left(\gamma w_n^\beta p_n^{-\beta} \right)^{-\theta}} = \frac{T_i}{T_n} \left(\frac{w_i}{w_n} \right)^{-\beta\theta} \left(\frac{p_i}{p_n} \right)^{\beta\theta}$$

Through simple manipulations I obtain the following price ratio:

$$\frac{p_i}{p_n} = \frac{w_i}{w_n} \left(\frac{T_n}{T_i} \right)^{\frac{1}{\beta\theta}} \left(\frac{\frac{X_{ii}}{X_i}}{\frac{X_{nn}}{X_n}} \right)^{\frac{1}{\beta\theta}}$$

Which is equivalent to:

$$\frac{p_i}{p_n} = \frac{w_i}{w_n} \left(\frac{T_i}{T_n} \right)^{-\frac{1}{\beta\theta}} \left(\frac{\frac{X_i}{X_{ii}}}{\frac{X_n}{X_{nn}}} \right)^{-\frac{1}{\beta\theta}}$$

By normalizing trade share by the importer home sales we obtain:

$$\frac{\frac{X_{ni}}{X_n}}{\frac{X_{nn}}{X_n}} = \frac{X_{ni}}{X_{nn}} = \frac{T_i}{T_n} \left(\frac{w_i}{w_n} \right)^{-\beta\theta} \left(\frac{p_i}{p_n} \right)^{-\theta(1-\beta)} d_{ni}^{-\theta}$$

By substituting the price ratio into the equation above I obtain the tranformed EK trade equation (6).
